Abstract. We systematically investigate the incremental response of various equilibrium states of dense 2D model granular materials, along the biaxial compression path ($\sigma_{11} < \sigma_{22}$, $\sigma_{12} = 0$). Stress increments are applied in arbitrary directions in 3-dimensional stress space ($\sigma_{11}, \sigma_{22}, \sigma_{12}$). In states with stable contact networks we compute the stiffness matrix and the elastic moduli, and separate elastic and irreversible strains in the range in which the latter are homogeneous functions of degree one of stress increments. Without principal stress axis rotation, the response abides by elastoplasticity with a Mohr-Coulomb criterion and a non-associated flow rule. However a nonelastic shear strain is also observed for increments of σ_{12} , and shear and in-plane responses couple. This behavior correlates to the distribution of friction mobilization and sliding at contacts.

Keywords: discrete element simulation; incremental behavior; elastoplasticity; flow rule; hardening

INTRODUCTION

Although the mechanical behavior of solidlike granular materials under quasistatic loading conditions is often modeled as elastoplastic at the continuum level [1, 2], there are still few studies addressing the microscopic origins of such a behavior by discrete, grain-level simulation [3–6]. To assess the applicability of elastoplastic laws, one needs to investigate the response to small stress or strain increments, superimposed in various directions on an equilibrium state. One essential motivation for such studies is the prediction of shear band formation, for which such criteria as the Rudnicki-Rice [7] condition involve the incremental response. In particular, localization is crucially sensitive to the response to stress increments with rotation of principal axes, as when some simple shear is superimposed on a biaxial compression [8]. The present study addresses this issue for the simplest model material, an assembly of disks in 2 dimensions, for which the response to load increments in all 3 dimensions of stress space is computed at various points along a biaxial loading path.

MODEL MATERIAL AND METHODS

Our simulation samples comprise 5600 disks enclosed in a periodic rectangular cell. The diameter distribution is uniform between $0.7d$ and $1.3d$. We use a simple, frictional-elastic contact model, involving (constant) normal contact stiffness K_N , tangential contact stiffness K_T (here we set $K_T = K_N$) and a friction coefficient, μ , set to 0.3. The normal (elastic) contact force is $F_N = K_N h$ where h is the interpenetration of contacting disks (which models surface deflection). The tangential force F_T re-

lates to the elastic part δ of the tangential relative displacement, as $F_T = K_T \delta$, and is incrementally computed to enforce the Coulomb condition $|F_T| \leq \mu F_N$. Some viscous damping is also introduced, which proves irrelevant to the material behavior for low enough strain rates.

We focus here on dense samples, which are initially assembled without friction, under an isotropic pressure P . The initial state is thus characterized by an isotropic fabric and a large coordination number (close to 4). The dimensionless stiffness parameter $\kappa = K_N/P$ sets the scale of contact deflections, as $h/d \propto \kappa^{-1}$. We choose value $\kappa = 10^4$ in most simulations.

Deformations of the simulation cell, i.e. macroscopic strains, are controlled, or vary in response to applied stresses. This is achieved with specific implementations of Parrinello-Rahman and Lees-Edwards techniques (first developed for molecular systems [9]), as explained in Ref. [10]. Stresses are given by the classical Love formula. In the biaxial compression test, the deformable cell remains rectangular, its edges parallel to the principal stress directions. Principal stress value σ_1 (the lateral stress) is kept equal to P , while σ_2 (the axial stress) increases in response to strain ϵ_2 , which grows at a controlled rate (compressive stresses and shrinking strains are positive). As indicated in Fig. 1, the compression test is stopped at different stages and the sample is equilibrated at constant stresses. This entails slight *creep* strain increments, which remain quite small (of order 10^{-6}), until equilibrium conditions are satisfied with good accuracy (the tolerance is 10^{-4} in units of P , dP , and d^2P for stresses, forces and moments, respectively). In those well-equilibrated intermediate states, hereafter referred to as *investigation points*, we first compute elastic moduli. To do so, we use the stiffness matrix associated to the contact network, as in Ref. [11]. It is conve-

FIGURE 1. Deviator stress versus axial strain curve, and location of 2 investigation points for incremental response

nient to denote stresses and strains as 3-vectors (as $\delta\vec{\sigma}$, $\delta\vec{\epsilon}$) with $\delta\sigma_3 = \sqrt{2}\sigma_{12}$, while notations $\delta\sigma_1$, $\delta\sigma_2$ keep the same meaning (and similarly for $\delta\vec{\epsilon}$). Due to symmetry about the principal axes there are four independent elastic moduli, which satisfy:

$$\delta\vec{\sigma} = \underline{\underline{\mathbf{C}}} \cdot \delta\vec{\epsilon}^E, \text{ with } \underline{\underline{\mathbf{C}}} = \begin{bmatrix} C_{11} & C_{12} & 0 \\ C_{12} & C_{22} & 0 \\ 0 & 0 & 2C_{33} \end{bmatrix} \quad (1)$$

superscripts E recalling that strains are purely elastic. The incremental response for various load directions is then computed, for different stress increments. We choose $\delta\vec{\sigma}$ values on a sphere in 3-space, centered at the origin, of radius $2\sqrt{2} \times 10^{-3}P$. Such increments are applied, and then multiplied by integer factors 2, 3... up to 12, in order to record the influence of both their direction and their amplitude. The calculations are fully stress-controlled, with variations of all 3 strain components. Once a new, perturbed equilibrium is reached, $\delta\vec{\epsilon}$ is measured, from which the elastic part $\delta\vec{\epsilon}^E = \underline{\underline{\mathbf{C}}}^{-1} \cdot \delta\vec{\sigma}$ is subtracted, defining the *irreversible* strain increment, which we denote with superscript P (for “plastic”). Investigation points with $\sigma_2/\sigma_1 = 1.2, 1.4, 1.6$ and 1.8 were studied

Before presenting the results in the next section, let us recall that as a consequence of the assembling process, the investigated states possess a large coordination number, and (see Fig. 1) are within the range of strain (“regime I”), along the biaxial loading curve, that is dominated by contact deformation [11, 12]. This means that the contact network does not break apart, and that the irreversible strains are due to sliding at contacts where the Coulomb limit is reached. As a consequence, macroscopic strains, on changing confining stresses or stiffness constants, scale as κ^{-1} [12]. For larger deviators, or in poorly coordinated samples (which might be very dense nevertheless [11]), the macroscopic strains stem from network ruptures and rearrangements (“regime II”) and the incremental behavior might differ.

FIGURE 2. Stress increments in principal axis plane

INCREMENTAL RESPONSE

No rotation of principal axes

We first investigate the response to stress increments lying in the plane of principal stresses (i.e., $\delta\sigma_3 = 0$). For each investigation point along the curve of Fig. 1, 12 different orientations of $\delta\vec{\sigma}$ in this plane are tested, as shown in Fig. 2, with 12 different amplitudes (as specified before). In order to assess the relevance of classical plasticity models for the material studied here we focus on the following three aspects: (i) the existence of a flow rule dictating the direction of $\delta\vec{\epsilon}^P$; (ii) at equal amplitude $|\delta\vec{\sigma}|$, the linear dependence of amplitude $|\delta\vec{\epsilon}^P|$ on the positive part $[\delta\vec{\sigma}]_+$ of $\delta\vec{\sigma} = \mathbf{N}_C \cdot \delta\vec{\sigma}$, where \mathbf{N}_C is the outer normal to some yield criterion in stress space; (iii) the same linear dependence for varying stress increment amplitudes. The existence of a plastic flow rule is a sharp feature arising from incremental tests, as shown in Fig. 3, corresponding to an investigation point with $\sigma_2/\sigma_1 = 1.4$. Elastic strain increments $\delta\epsilon_1^E$ and $\delta\epsilon_2^E$ are disposed along as many directions as the stress increments in Fig. 2, while plastic strain increments ($\delta\epsilon_1^P$ and $\delta\epsilon_2^P$) clearly align along a unique direction, consistently with the flow rule. The same features are observed for all investigation points.

We discuss point (ii) of our list by referring to Fig. 4 in which $|\delta\vec{\epsilon}^P|$ is plotted versus the angle α between principal axis 1 and increment $\delta\vec{\sigma}$, at constant amplitude $|\delta\vec{\sigma}|$. In the framework of classical plasticity these values should fit to the positive part of a cosine function reaching its maximum in normal to the yield criterion. Fitting theoretical curves to data allows to estimate the angle α_{NYC} characterising the normal \mathbf{N}_C to the yield criterion [4] and the maximal amplitude $\delta\epsilon_{MAX}^P$ of the plastic strain increment. Notably, for all investigation points, the normal \mathbf{N}_C , oriented at angle α_{NYC} , is consistently very nearly orthogonal to the current stress direction σ_1, σ_2 (oriented at angle α_{LD} in stress space). This suggests that the yield criterion might be defined by the Coulomb

condition of a constant ratio σ_2/σ_1 . Since $\alpha_{PFD} \neq \alpha_{NYC}$ the plastic flow direction differs from the normal \mathbf{N}_C , as in *nonassociated elastoplasticity*. As to point (iii), it is

FIGURE 5. Nonelastic strain amplitude vs. $[\delta \hat{\sigma}]_+$ defined with normal to criterion identified in Fig. 4.

checked in Fig. 5, from which the following *plastic moduli* C_P (in units of K_N) are measured: $C_P = ??, ??, ??, ??$ corresponding, respectively, to $\sigma_2/\sigma_1 = 1.2, 1.4, 1.6$ and 1.8 .

General case

If elastoplasticity applies – which seems to be the case for $\delta \vec{\sigma}$ in the plane of the principal stress directions – then a small load increment in the third direction, $\delta \sigma_3 \neq 0$, $\delta \sigma_1 = \delta \sigma_2 = 0$ should entail a purely elastic response. Fig. 6 contradicts this prediction, as a nonelastic shear strain $\delta \epsilon_3^P$ immediately appears, which increase proportionally to shear stress $|\sigma_{12}|$. Coefficients can be slightly different for positive and negative $\delta \sigma_{12}$ because of finite sample size effects. Like in-plane increments, such $\delta \vec{\sigma}$, if extremely small, yield a nonelastic response that is slightly sublinear in their amplitude, but a plastic modulus can be identified for $\delta \sigma_3/P$ of order 10^{-2} . Out-of-plane increments $\delta \vec{\sigma}$ also entail plastic strains

FIGURE 6. Total, elastic, nonelastic shear strains as functions of applied shear stress to state with $\sigma_2/\sigma_1 = 1.8$. Plastic modulus is close to $3K_N$ (resp. $2.8K_N$) for $\delta \sigma_{12} > 0$ ($\delta \sigma_{12} < 0$).

$\delta \epsilon_1^P$, $\delta \epsilon_2^P$, which are still related by the same flow rule as previously identified for in-plane loads ($\delta \sigma_3 = 0$). Fig. 7 gathers results both from 16 load directions for which $\delta \sigma_3 = \pm \sqrt{\delta \sigma_1^2 + \delta \sigma_2^2}$, as well as simple shear increments ($\delta \sigma_1 = \delta \sigma_2 = 0$) with both signs of $\delta \sigma_3$. Quite surprisingly, the latter also produce a nonelastic re-

FIGURE 7. Analog of Fig. 3 in state with $\sigma_2/\sigma_1 = 1.8$, for out-of-plane $\delta \vec{\sigma}$. Big red dots correspond to $\delta \sigma_1 = \delta \sigma_2 = 0$. Elastic strains (bottom right) are comparatively smaller.

ponse in the plane of principal stresses. We thus observe

that both the irreversible strains and the stress increments causing them span two-dimensional spaces, with one in-plane and one out-of-plane direction, and that the response couples both directions. To be complete, we should then specify how $\delta\vec{\epsilon}^P$ depends on $\delta\vec{\sigma}$ for all load increments. Although we are still investigating this issue, some preliminary attempts at superposition of responses to shear and to in-plane stress increments are encouraging, as shown by Fig. 8. Upon superimposing the pre-

FIGURE 8. Predicted, with procedure defined in text, versus observed $\delta\epsilon_2$ for combined loads ($\sigma_2/\sigma_1 = 1.8$).

viously identified responses to (in-plane) $\delta\hat{\sigma} = \mathbf{N}_C \cdot \delta\vec{\sigma}$ and to $|\delta\sigma_3|$ in simple shear, Fig. 8 shows that the predicted values are fairly close to the measured ones.

MICROSCOPIC ASPECTS

The macroscopic nonelastic is due to plastic sliding in some contacts. While the distribution of contact orientations (fabric) is still moderately anisotropic in the investigated states, the sliding contact fabric (Fig. 9) has a much stronger angular dependence. Such a distribution

FIGURE 9. Left: sliding contact orientational distribution (major principal axis vertical on the plot), normalized such that its angular average is a coordination number. Diameter of circle is 1.1, global coordination is 3.5. Right: angular distribution of amplitude of sliding relative displacement in contacts in response to in-plane load increment, normalized by plastic strain. $\sigma_2/\sigma_1 = 1.8$.

is observed for $\delta\hat{\sigma} > 0$, while the population of sliding contacts virtually vanishes on applying $\delta\hat{\sigma} < 0$ and $\delta\sigma_3 = 0$. The sliding contact fabric depends on both $\delta\sigma_3$ and $\delta\hat{\sigma}$ in general. A nonzero $\delta\sigma_3$ breaks its symmetry. The angular distribution of sliding displacements at contacts (Fig. 9), albeit different, is also strongly anisotropic and shows similar sensitivity to the direction of $\delta\vec{\sigma}$. Finally, stress increments for which $\delta\vec{\sigma}$ is proportional to $\vec{\sigma}$ (the neutral direction), entail no sliding, as contact forces tend to increase proportionally to their previous value.

PERSPECTIVES

The essential finding of the present study, which still remains to be systematized and calls for more thorough micromechanical investigations, is the correspondence between 2D stress increments orthogonal to the current stress level and nonelastic strains belonging to a 2D space. In the near future we plan to formulate it as a complete constitutive incremental law, to relate it to microscopic phenomena and to use it in localization criteria. The incremental response in systems with gradually rearranging contact networks (“regime II”, associated with microscopic instabilities) should also be investigated.
